# MODELLING OF CONSOLIDATION BEHAVIOUR OF SOIL 

## A Project report

by
MD. HABIBULLAH

Submitted to the Department of Civil Engineering Bangladesh University of Engineering \& Technology, Dhaka
in partial fulfillment of the requirements for the degree
of
MASTER OF ENGINEERING IN CIVIL ENGINEERING

Dedicated to
my brother
MD. NAZRUL ISLAM
(ii)

## DECLARATION

I hereby declare that the project work presented herewith has been performed by me and that this work has not been submitted for any other degree previously.

(MD. HABIBULLAH)

## ACKNOWLEDGEMENTS

## (All praises to Almighty Allah)

The author expresses his heartiest appreciation to his supervisor, Dr. Sarwar Jahan Md. Yasin Associate professor, Department of Civil Engineering, BUET, Dhaka, for his continued encouragement and guidance in the research. His keen interest in this topic and valuable suggestions, constructive criticisms and advice at every stage made this research possible.

The author also expresses his profound gratitude to Dr. A. M. M. Safiullah and Dr. Md. Zoynul Abedin both Professors of the Department of Civil Engineering, BUET, Dhaka, for their time and effort in reading this report and making valuable suggestions.

Sincere appreciation goes to colleagues and friends for their help and suggestions at different stage of the work.

Assistance provided by Mr. Habibur Rahman and Md. Alimuddin, both staffs of the Geotechnical Engineering Laboratory, is duly acknowledged.

Finally, the author expresses his gratitude and appreciation to his parents, brothers and relatives for their inspiration and encouragement.

#### Abstract

Routine laboratory consolidation test, though simple in procedure, involves a long time (about a week) and hence cost. Also, the determination of parameters for estimation of settlement and rate of settlement is tedious. After involving such time and effort, the amount of total settlement and rate of settlement estimated from test data vary significantly from field observations. It was, therefore, envisaged that use of the one-dimensional test with a pressure increment ratio larger than that used in conventional tests (thereby reducing the load steps, and time) together with a suitable mathematical model may produce the settlement information of a soil layer for a lesser time and effort. The model will also facilitate implementation of computational methods such as finite element method in settlement estimation. With these objectives, a simple mathematical function is proposed that can represent the void ratio $\sim$ time relations (or dial reading $\sim$ time relations) observed in a one dimensional consolidation test on clay soil. The model consists of three parameters. The role and physical significance of each parameter is explained.

To verify the effectiveness of the model, consolidation tests were performed on specimens from soil cakes reconstituted in the laboratory under two different vertical pressures ( 50 kPa and 100 kPa ). Tests were performed with pressure increment ratios of 2 (used in conventional tests) and 4. The nature and amount of variation of the model parameters were determined from these tests. Comparison of $\mathrm{e} \sim \mathrm{t}$, $\mathrm{e} \sim \sigma^{\prime}$ relations from test data and that back calculated using the model showed reasonably good agreement testifying the effectiveness of the model.

It was observed that there is virtually no effect of using a pressure increment ratio of 4 instead 2 on the model parameters. Therefore, it is suggested that routine consolidation tests may be performed with a larger pressure increment ratio, especially in cases where the range of pressure to be investigated is large, together with the model without sacrificing accuracy. The values of $c_{v}$ at intermediate pressure levels can be obtained from the model.

## LIST OF SYMBOL

$\sigma=$ Total stress
$\sigma^{\prime}=$ Effective stress
$e=$ Void ratio
$\mathrm{S}_{\mathrm{c}}=$ Consolidation settlement
$\mathrm{C}_{\mathrm{c}}=$ Compression index
$\mathrm{w}_{\mathrm{n}}=$ Natural moisture content
$\mathrm{LL}=$ Liquid limit
$\mathrm{PI}=$ Plasticity index
$\mathrm{U}_{\mathrm{v}}=$ Degree of consolidation
$\mathrm{T}_{\mathrm{v}}=$ Non dimensional time factor
$\mathrm{K}=$ Coefficient of permeability
$\mathrm{i}=$ Hydraulic gradient
Reconstituted $=$ Term for a clay soil which has been remoulded at a water content of between one and one and half time the liquid, without air or oven drying and then consolidated under one-dimensional consolidation.

Remoulded $=$ Term for a clay soil which has been remoulded without changing its moisture contend.

## Chapter 1 <br> INTRODUCTION

### 1.1 Introduction

All soils are compressible, in that they undergo volume changes when they are subjected to changes in the stresses applied to them. The resulting compression is relatively large when drainage is allowed. However, the magnitude of settlement is of engineering significance when reference is made to the tolerable settlement for the structure concerned. Since the introduction of Terzaghi's consolidartion theory, a great number of contributions have been made for predicting the magnitude and rate of settlement by introducing more refined soil models and less restricted assumptions on the parameters describing these models. In spite of all these improvements, prediction of settlement has remained more an art than a routine procedure. While it is possible today to predict the magnitude of total settlement within 10 to $20 \%$ in many cases, the capability of predicting time settlement relationships has remained rather poor (Balasubramanium, 1981). It is therefore not surprising that Terzaghi's onedimensional consolidation theory and one-dimensional consolidation test is widely used by practicing engineers, even in case where the loading conditions are far from one-dimensional.

### 1.2 Objectives of the present study

The one-dimensional consolidation test, though simple is lengthy and the calculation for obtaining parameters is also tedious. So, it was conceived that if a mathematical model could be established for the time dial reading curves under any load increment and the magnitude and trend of variation of the model parameters for different test conditions could be known then a consolidation test using one or two load increment might be used. Thus, savings in both time and cost could be made without sacrificing much accuracy. With this view, the following objectives were set for the present study:
(1) To find the effect(s) of initial pressure, load increment ratio, pre-consolidation pressure etc. on
(a) $\mathrm{e} \sim \sigma^{\prime}$ and $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ relations
(b) Compression index, $\mathrm{C}_{\mathrm{c}}$
(c) Coefficient of consolidation, $\mathrm{C}_{\mathrm{V}}$
(2) To search for a suitable mathematical function (a mathematical model) which can be used to represent dial reading vs. time (or void ratio vs. time) relations as obtained in a consolidation test for a certain pressure.
(3) To provide physical and meaningful interpretation of the parameters.
(4) To determine model parameters for different pressure increment and thus to establish correlations between these parameters and pressure or pressure increment ratio so that $\mathrm{e} \sim \sigma^{\prime}$ and $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ plots can be obtained.
(5) To find the effect(s) of initial pressure, load increment ratio, pre-consolidation pressure etc. on the model parameters.

### 1.3 The test program

Reconstituted sample was prepared from clay slurry under overburden pressures of 50 and 100 kPa . The purpose of using reconstituted soil is to obtain a homogeneous soil layer with a known stress history. The clay was obtained from an excavation in Dhaka city from a depth of about 10 m . One dimensional compression test was then performed on these specimens to reveal the effects of several factors such as load increment ratio, initial pressure etc. on pre-consolidation pressure $\sigma_{c}^{\prime}$, compression index $\mathrm{C}_{\mathrm{c}}$, coefficient of consolidation $\mathrm{c}_{\mathrm{v}}$ etc. The data is also used to find the variation of the three parameters of a proposed model from which the void ratio $\sim$ time plots and void ratio $\sim$ pressure plots can be generated and thus be useful for settlement analysis using numerical techniques of finite element.

## Chapter 2

## LITERATURE REVIEW

### 2.1 Introduction

A settlement analysis usually consists of (1) an assessment of the stress increment in the compressible layer by the imposed load, and (2) the evaluation of the settlement caused by the stress increment using an appropriate stress-strain relationship of the soil. Settlements are classified as immediate, consolidation and creep settlement. Of these three types of settlements, consolidation settlement is usually the major contributor to total settlement. Consolidation is an important fundamental phenomenon causing ground settlement and must be understood to solve geotechnical problems. Although numerical methods, such as finite element, has enabled three dimensional analysis of soil medium, the theory of one dimensional consolidation and parameters from one dimensional consolidation test (oedometer test) is still largely used to estimate total consolidation settlement and the rate of settlement. In this chapter, the process of consolidation, the one-dimensional theory of consolidation, the laboratory test, determination of the related parameters and their variation etc. are discussed.

### 2.2 The process of consolidation

All soils undergo compression when they are subjected to increase in the stresses applied to them. If the soil is initially saturated then the stress increase causes instantaneous increase in the pore-water pressure and initially the added load is carried entirely by the water medium. Due to the excess-pore pressure, the pore water tends to escape through the drainage paths and with time the load is transferred from the water to the soil skeleton. This process of dissipation of excess pore-water pressure accompanied by gradual transfer of load from the pore fluid to the soil skeleton is termed as consolidation. According to Terzaghi (1943) " a decrease of water content of a saturated soil without replacement of the water by air is called a process of consolidation".

Fig.2.1 Terzaghi's one-dimensional consolidation model

Fig.2.2 Stress~Time curve

Terzaghi (1943) suggested the model shown in Fig.2.1 to illustrate the process of consolidation. Here the steel springs represent the soil. It is assumed that the frictionless piston is supported by the springs and the cylinder is filled with water. If a load is applied to the piston with the valve closed, the length of the springs remain unchanged since water is incompressible (assumed). If the load induces an increase in total stress of $\Delta \sigma$, then the whole of this must be taken up by an equal increase in pore water pressure (Fig.2.2). When the valve is opened, the excess pore water pressure causes the water to flow out, the pore water pressure decreases and the piston sinks as the springs are compressed. Thus, the load is gradually transferred to the springs, causing them to shorten, until it is all carried by the springs. At the final stage, therefore, the increase in effective stress is equal to the increase in total stress and the excess pore water pressure reduces to zero. The rate of compression obviously depends on the extent to which the valve is opened; this is analogous to the permeability of the soil.

### 2.3 The one-dimensional consolidation test and its interpretation

The compressibility characteristics of a soil layer, in terms of the amount and rate of settlement, are usually determined from the one-dimensional consolidation test. This test is detailed in ASTM D-2435 (ASTM, 1986).

The apparatus used is called an oedometer (Fig.2.3). A soil specimen in the form of a disc [ 63.5 mm diameter ( 2.5 inch ) and 25.4 mm ( 1 inch ) thickness in standard test] is cut out from a soil cake. The specimen, enclosed in a metal ring, is sandwiched between two porous stone discs. There may be two types of assembly of the metal ring, soil specimen and porous discs;
(1) Floating ring type: Both the top and bottom porous stone discs are slightly smaller than the metal ring (Fig.2.3a). Both the top and bottom porous stones provide vertical and lateral drainage. Compression takes place from both the faces of the soil specimen.

Fig.2.3 The ocdometer cell (a) Floating ring (b) \& (c) Fixed ring
(2) Fixed ring type: The top porous disc is slightly smaller than the metal ring. The bottom porous stone may be either smaller or larger than the metal ring. If the bottom porous stone is larger than the metal ring then the metal ring rests on the bottom porous disc (Fig.2.3b). In case the bottom porous stone is slightly smaller than the metal ring, then the metal ring touches the bottom of the container (Fig.2.3c). Soil specimen is compressed from the top face only.

The metal ring, specimen and porous stone assembly is placed in the cell (a container with the top open), which is then filled with water. A vertical static load is then applied through a lever system. The porous stones allow the excess pore pressure, due to load increment, to freely escape as the soil voids are compressed. The change in thickness of the sample is recorded by means of a dial gauge or LVDT (linear variable displacement transducer). Readings are recorded at certain intervals of time and continued until the specimen is fully consolidated under the current load increment. Bowels (1984) suggests that this may be taken as the time when the dial reading has remained relatively unchanged for three successive readings, where the elapsed time of each reading is approximately double that of the previous reading. In conventional laboratory tests, loads are changed every 24 hour, which is generally satisfactory for samples of 2 to 3 cm thickness. The pressure applied at the first stage is normally equal to the in-situ vertical stress at the depth from which the sample was obtained, except for soft and very soft clays, when a lower value must be used. Further pressure increments are then applied each being double the previous increment producing a ratio of $\Delta \sigma / \sigma^{\prime}=1$ (Leonards,1962). A typical sequence is $25,50,100,200,400,800$, $1600,3200 \mathrm{kPa}$ or $0.25,0.5,1,2,4,8,16 \mathrm{tsf}$. There is evidence (Leonards, 1962) that if the initial pressure increment is too low, the excess pore pressure may not be sufficient to initiate pore water flow in some clay soils. It is reported (Bowels, 1984) that initial pressure of the order of 25 kPa appear adequate to avoid it. The value of final pressure depends on the type of soil and on the magnitude of stress anticipated on site. The specimen is kept under water throughout the test.

After full consolidation is reached under the final load, the load is removed either in one or in several stages.

### 2.3.1 e versus $\sigma^{\prime}$ curve

The data collected from a consolidation test enable to relate the change in void ratio to the change in effective stress. Usually the void ratio is plotted against the effective stress as shown in Fig.2.4. This curve provides the most direct method of computing the consolidation settlement for a known stress increment.

Suppose a stratum of clay of thickness $\mathrm{H}_{0}$ is subjected to a change in effective stress from $\sigma_{0}^{\prime}$ to $\sigma_{1}^{\prime}$. From e versus $\sigma^{\prime}$ curve the corresponding values of void ratio, $\mathrm{e}_{0}$ and $e_{1}$ are obtained and then the consolidation settlement is calculated as :
Consolidation settlement, $S_{c}=\Delta H=\frac{e_{0}-e_{1}}{1+e_{0}} \cdot H_{0}$

### 2.3.2 Prediction of pre-consolidation pressure

If a soil layer has been subjected, some times in the past in its loading history, to a magnitude of effective stress greater than that now exists, then that soil layer is said to be over consolidated and the past maximum effective stress is said to be its preconsolidation pressure, $\sigma_{c}^{\prime}$. Otherwise the soil is said to be normally consolidated. $\sigma_{c}^{\prime}$ enables an assessment of the degree of over consolidation expressed in terms of over consolidation ratio (OCR).
$\mathrm{OCR}=\frac{\sigma_{\mathrm{c}}^{\prime}}{\sigma_{0}^{\prime}}=\frac{\text { Previous maxium effective stress }}{\text { Present effective stress }}$
The significance of $\sigma_{c}{ }_{c}$ for an over consolidated clay is that, if stresses are kept below this value, settlement can be expected to be small. However, if the applied stresses due to loading exceed $\sigma_{c}^{\prime}$, then large settlement will occur. The OCR has also significant influence on different parameters (such as shear strength) for most soils.

Casagrande (1936) suggested a graphical method based on $e \sim \log (\sigma)$ ' curve to determine the pre-consolidation pressure (Fig.2.5). The steps are as follows:

1. The point $P$ that has the maximum curvature on the upper curved portion of the $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ is located by visual estimation.
2. A horizontal line PQ is drawn at P .

Fig.2.4 Void ratio vs. effective stress curve

Fig.2.5 Procedure for determination of preconsolidation pressure by Casagrande's method
3. A tangent line $P R$ is drawn at $P$.
4. A line $P S$ is drawn at $P$ that bisects the angle $Q P R$.
5. The bottom straight line portion of the e $\sim \log \left(\sigma^{\prime}\right)$ plot is extended backward to intersect the bisector PS at T.
6. The effective pressure corresponding to point T is the pre-consolidation pressure $\sigma_{c}$.

### 2.3.3 The compression index, $\mathrm{C}_{\mathrm{c}}$

The slope of the e $\sim \log \left(\sigma^{\prime}\right)$ plot for normally consolidated soil is referred to as the compression index $\mathrm{C}_{\mathrm{c}}$. From Fig.2.6.
$C_{c}=\frac{\Delta e}{\Delta\left[\log \left(\sigma^{\prime}\right)\right]}=\frac{e_{0}-e_{1}}{\log \left(\sigma_{1}^{\prime}\right)-\log \left(\sigma_{0}^{\prime}\right)}=\frac{e_{0}-e_{1}}{\log \left(\frac{\sigma_{1}^{\prime}}{\sigma_{0}^{\prime}}\right)}$
The void ratio for a given change in effective stress may, therefore, be obtained as
$e_{1}=e_{0}-C_{c} \log \left(\frac{\sigma_{1}^{\prime}}{\sigma_{0}^{\prime}}\right)$
If the soil acts as a normally consolidated clay due to the change of effective stress then settlement can be obtained by using $\mathrm{C}_{\mathrm{c}}$. From equation 2.3 :
$\Delta e=e_{0}-e_{1}=C_{c} \log \left(\frac{\sigma_{1}^{\prime}}{\sigma_{0}^{\prime}}\right)$
Substituting $\Delta \mathrm{e}$ from equation 2.4 into equation 2.1,
Consolidation settlement, $\mathrm{S}_{\mathrm{c}}=\frac{\mathrm{C}_{\mathrm{c}}}{1+\mathrm{e}_{0}} \cdot \log \left(\frac{\sigma_{1}^{\prime}}{\sigma_{0}^{\prime}}\right) \cdot \mathrm{H}_{0}$
Several correlations exist in literature for the value of $\mathrm{C}_{\mathrm{c}}$. Terzaghi and Peck (1967) gave a correlation for the compression index as

$$
\begin{equation*}
\mathrm{C}_{\mathrm{c}}=0.009(\mathrm{LL}-10) \tag{2.6}
\end{equation*}
$$

where LL is the liquid limit. This relation is reported to have a reliability in the range of $\pm 30 \%$ and should not be used for clays with sensitivity ratios greater than 4 . For remoulded clay Terzaghi and Peck (1967) suggested the following relation

$$
\begin{equation*}
C_{c}=0.007(\text { LL-10 }) \tag{2.7}
\end{equation*}
$$

Fig.2.6 Compression index $\mathrm{C}_{\mathrm{c}}$

Azzouz et al. (1976) has correlated compression index with basic soil properties for different types of clays which are presented in Table 2.1 here from Das(1983).

Table 2.1 Empirical equations for $\mathrm{C}_{\mathrm{c}}$.

| Equation | Regions of applicability |
| :--- | :--- |
| $\mathrm{C}_{\mathrm{c}}=0.01 \mathrm{w}_{\mathrm{n}}$ | Chicago clay |
| $\mathrm{C}_{\mathrm{c}}=0.0046($ LL-9 $)$ | Brazilian Clay |
| $\mathrm{C}_{\mathrm{c}}=1.21+1.055\left(\mathrm{e}_{0}-1.87\right)$ | Motley clays from Sao Paulo city |
| $\mathrm{C}_{\mathrm{c}}=0.208 \mathrm{e}_{0}+0.0083$ | Chicago clays |
| $\mathrm{C}_{\mathrm{c}}=0.0115 \mathrm{w}_{\mathrm{n}}$ | Organic soil, peats |
| $\mathrm{C}_{\mathrm{c}}=0.02+0.014(\mathrm{PI})$ | Natural deep ocean soil samples from the <br> North Atlantic (Nacci et al. (1975) |

$\mathrm{w}_{\mathrm{n}}=$ natural moisture content (\%), $\mathrm{e}_{0}=$ in situ void ratio,
$\mathrm{LL}=$ Liquid limit, $\mathrm{Pl}=$ Plasticity index.

### 2.3.4 Coefficient of volume compressibility, $\mathrm{m}_{\mathrm{v}}$

The coefficient of volume compressibility $\left(\mathrm{m}_{\mathrm{v}}\right)$ is defined as the amount of change in unit volume of soil that results from a unit increase in effective stress. The value of $m_{v}$ is not constant for a given soil but varies with the level of effective stress i.e.
$\mathrm{m}_{\mathrm{v}}=\frac{\varepsilon_{\mathrm{vol}}}{\Delta \sigma^{\prime}}=\frac{\Delta \mathrm{V}}{\mathrm{V}_{0}} \cdot \Delta \sigma^{\prime}$

In a one-dimensional consolidation test it may be reasonably assumed (if the consolidation ring is thick enough) that no change in lateral dimension takes place and there is only a change in thickness of the specimen. The change in volume $\Delta \mathrm{V}$ of the specimen which results from an increase in effective stress $\left(\Delta \sigma^{\prime}\right)$ may, therefore, be represented by either the change in thickness $(\Delta \mathrm{H})$ or the change in void ratio $(\Delta \mathrm{e})$. The volumetric strain of a layer initially $\mathrm{H}_{0}$ thick can be expressed as

$$
\begin{equation*}
\frac{\Delta \mathrm{V}}{\mathrm{~V}_{0}}=\frac{\Delta \mathrm{H}}{\mathrm{H}_{0}}=\frac{\Delta \mathrm{e}}{1+\mathrm{e}_{0}} \tag{2.9}
\end{equation*}
$$

Combining 2.8 and 2.9

$$
\begin{equation*}
\mathrm{m}_{\mathrm{v}}=\frac{\Delta \mathrm{H}}{\mathrm{H}_{0}} \cdot \frac{1}{\Delta \sigma^{\prime}}=\frac{\Delta \mathrm{e}}{\Delta \sigma^{\prime}} \cdot \frac{1}{1+\mathrm{e}_{0}} \tag{2.10}
\end{equation*}
$$

where $\Delta \mathrm{e} / \Delta \sigma^{\prime}$ is the slope of the e vs. $\sigma^{\prime}$ curve.
Now the consolidation settlement can be obtained as (from equation 2.10)
$\mathrm{S}_{\mathrm{c}}=\Delta \mathrm{H}=\mathrm{m}_{\mathrm{v}} \cdot \Delta \sigma^{\prime} . \mathrm{H}_{0}$
$\mathrm{m}_{\mathrm{v}}$ may also be considered as the reciprocal of constrained modulus, $\mathrm{E}_{0}^{\prime}$ :
$\mathrm{m}_{\mathrm{v}}=\frac{1}{\Delta \sigma^{\prime} / \varepsilon_{\mathrm{vol}}}=\frac{1}{\mathrm{E}_{0}^{\prime}}$

### 2.3.5 Time rate of consolidation : Co-efficient of consolidation $c_{v}$

It is important to estimate the rate of settlement of a structure so that if the total estimated settlement $\Delta H$ is large, an estimate of the time span over which significant portion of the settlement will take place can be anticipated. However, if the total settlement is small, its rate is usually of little importance. The settlement rate can be estimated using the coefficient of consolidation, $c_{v}$. Determination of the coefficient of consolidation is based on the theory of one-dimensional consolidation proposed by Terzaghi $(1925,1943)$. The theory considers the rate at which water is squeezed out of an element of soil and can be used to determine the rates of:
a) volume change of the soil with time
b) settlement of the soil with time
c) pore pressure dissipation with time

The underlying assumptions in the derivation of the mathematical equations are as follows:

1. The clay layer is homogeneous
2. The clay layer is saturated
3. Both water and soil particles are incompressible.
4. Deformation of the soil layer and flow of fluid is one-dimensional and in the direction of the applied stress.
5. The change in volume and thus void ratio is due to the squeezing out of the pore water only.
6. Darcy's law of water flow applies.
7. The load is applied instantaneously and over the whole of the soil layer.

In Fig.2.7 a layer of clay is shown to be subjected to a sudden increase in total vertical stress $\Delta \sigma_{1}$ which is distributed over a semi-infinite area. The layer is located between two highly permeable sand layers. Now, let us consider an elemental layer, within the clay stratum, of thickness dz , in which at time t , the excess pore water pressure is u . If a hypothetical standpipe is introduced (as shown in Fig.2.7) it can be seen that the fall in pore water pressure across the element is dh .

Fig. 2.8 shows a prismatic portion of the elemental layer having dimentions $\mathrm{dx}, \mathrm{dy}$ and dz . The drainage across the sample is one dimensional in the z direction, with a hydraulic gradient of $\frac{\partial h}{\partial z}$. According to Darcy's law the flow condition will be :
Flow in : $\mathrm{q}_{\mathrm{z}}=\mathrm{vA}=\mathrm{kiA}=\mathrm{k} \frac{\partial \mathrm{h}}{\partial \mathrm{z}} \mathrm{dx} d y$
Flow out : $q_{\text {out }}=k(i+d i) d x d y$

$$
\begin{equation*}
=\mathrm{k} \cdot\left(\frac{\partial \mathrm{~h}}{\partial \mathrm{z}}+\frac{\partial^{2} \mathrm{~h}}{\partial \mathrm{z}^{2}} \mathrm{dz}\right) \cdot \mathrm{dx} \mathrm{dy} \tag{2.14}
\end{equation*}
$$

where $\mathrm{k}=$ coefficient of permeability and $\mathrm{i}=$ hydraulic gradient.
Net rate of flow out of the element is therefore : $q_{\text {out }}-q_{\text {in }}=k \cdot \frac{\partial^{2} h}{\partial z^{2}} d x d y d z$

Volume of void in the soil element is $V_{v}=e_{s}$
Therefore, rate of change of volume of void is

$$
\begin{equation*}
\frac{\partial V_{v}}{\partial \mathrm{t}}=\mathrm{V}_{\mathrm{s}} \frac{\partial \mathrm{e}}{\partial \mathrm{t}}=\frac{\mathrm{V}}{1+\mathrm{e}} \cdot \frac{\partial \mathrm{e}}{\partial \mathrm{t}}=\frac{\mathrm{dxdydz}}{1+\mathrm{e}} \cdot \frac{\partial \mathrm{e}}{\partial \mathrm{t}} \tag{2.17}
\end{equation*}
$$

Now the rate of flow out of the element must be equal to the change of volume of voids :
Therefore : $k \cdot \frac{\partial^{2} h}{\partial z^{2}} d x d y d z=\frac{d x d y d z}{1+e} \cdot \frac{\partial e}{\partial t}$
i.e. $k \cdot \frac{\partial^{2} h}{\partial z^{2}}=\frac{1}{1+e} \cdot \frac{\partial \mathrm{e}}{\partial \mathrm{t}}$

But, $\mathrm{h}=\frac{\mathrm{u}}{\gamma_{\mathrm{w}}}$
$\therefore \frac{\mathrm{k}}{\gamma_{\mathrm{w}}} \cdot \frac{\partial^{2} \mathrm{u}}{\partial \mathrm{z}^{2}}=\frac{1}{1+\mathrm{e}} \cdot \frac{\partial \mathrm{e}}{\partial \mathrm{t}}$

(a)
(b)

Fig.2.7 Distribution of excess pore pressure in a clay layer subject to a uniform increase in vertical stress (a) Sectional elevation (b) Excess pore pressure distribution

Fig.2.8 One dimensional flow through a prismatic element.

The change in void ratio $\partial \mathrm{e}$ is due to the increase in effective stress; assuming that these are linearly related, then

$$
\begin{equation*}
\partial \mathrm{e}=-\mathrm{a}_{\mathrm{v}} \partial \sigma^{\prime} \tag{2.20}
\end{equation*}
$$

where $\mathrm{a}_{\mathrm{v}}$ is the coefficient of compressibility. The negative sign in equation 2.20 implies that if $\sigma^{\prime}$ increase, void ratio decreases.

Again total stress $\sigma$ remain constant and $\sigma^{\prime}=\sigma-u$; so that $\partial \sigma^{\prime}=-\partial u$
From equations 2.20 and 2.21

$$
\begin{equation*}
\partial \mathrm{e}=\mathrm{a}_{\mathrm{v}} \partial \mathrm{u} \tag{2.22}
\end{equation*}
$$

Substituting 2.22 into 2.19

$$
\begin{equation*}
\frac{\mathrm{k}}{\gamma_{\mathrm{w}}} \cdot \frac{\partial^{2} \mathrm{u}}{\partial \mathrm{z}^{2}}=\frac{\mathrm{a}_{\mathrm{v}}}{1+\mathrm{e}} \cdot \frac{\partial \mathrm{u}}{\partial \mathrm{t}} \tag{2.23}
\end{equation*}
$$

Again $m_{v}=\frac{\partial \mathrm{e}}{\partial \sigma^{\prime}} \cdot \frac{1}{1+\mathrm{e}} \quad$ [ from equation 2.10]

$$
\begin{equation*}
=\frac{a_{v}}{1+e} \tag{2.24}
\end{equation*}
$$

$\mathrm{m}_{\mathrm{v}}=$ coefficient of volume compressibility
$\therefore \frac{\mathrm{k}}{\gamma_{\mathrm{w}}} \cdot \frac{\partial^{2} \mathrm{u}}{\partial \mathrm{z}^{2}}=\mathrm{m}_{\mathrm{v}} \cdot \frac{\partial \mathrm{u}}{\partial \mathrm{t}}$ or $\quad \frac{\partial u}{\partial t}=\frac{k}{m_{v} \gamma_{w}} \cdot \frac{\partial^{2} u}{\partial z^{2}}$
where $c_{v}=$ coefficient of consolidation $=\frac{k}{m_{v} \gamma_{w}}$
Equation 2.25 is the basic differential equation of Terzaghi's consolidation theory. In order to obtain a solution to equation 2.25 the following non-dimensional factors are substituted

Degree of consolidation, $U_{v}=\frac{e_{0}-e}{e_{0}-e_{f}}=\frac{u_{0}-u}{u_{0}}$
Time factor $\mathrm{T}_{\mathrm{v}}=\frac{\mathrm{c}_{\mathrm{v}} \mathrm{t}}{\mathrm{d}^{2}}$
Drainage path ratio $Z=\frac{z}{d}$
where $\mathrm{e}_{0}=$ initial void ratio
$\mathrm{e}=$ void ratio after time t
$e_{\mathrm{f}}=$ final void ratio
$\mathrm{u}_{0}=$ initial excess pore water pressure
$\mathrm{u}=$ excess porewater pressure after time t
$d=$ length of drainage path
Substituting the above non-dimensional factors the one dimensional consolidation equation becomes

$$
\begin{equation*}
\frac{\partial^{2} \mathrm{U}_{\mathrm{v}}}{\partial \mathrm{Z}^{2}}=\frac{\partial \mathrm{U}_{\mathrm{v}}}{\partial \mathrm{~T}_{\mathrm{v}}} \tag{2.30}
\end{equation*}
$$

The solution to the above equation is obtained as
$U_{v}=1-\sum_{m=0}^{\infty} \frac{2}{M} \operatorname{Sin}(M Z) e^{-M^{2} T_{v}}$
where $\mathrm{M}=\frac{\pi}{2}(2 \mathrm{~m}+1) \quad \mathrm{m}=0,1,2 \ldots$. etc
Equation 2.31 merely relates the three parameters $U_{v}, Z$ and $T_{v}$ and these are conveniently represented as a graph of $U_{v}$ versus $Z$ for different $T_{v}$ values (Fig.2.9). The curved lines refer to constant values of time (or $\mathrm{T}_{\mathrm{v}}$ ) and so are called isochrones.

The value of coefficient of consolidation $\mathrm{c}_{\mathrm{v}}$ for a particular pressure increment in the consolidation test is determined by comparing the characteristics of time vs. dial reading plot. (from test data) and that for $U_{v}$ vs. $T_{v}$ (theoretical curve), the process being known as curve fitting. There are two curve fitting methods: (1) Square-root of time method (2) Logarithm-of-time method.

## Square-root of time method

Taylor (1942) showed that the Terzaghi theory of one dimensional consolidation gave a straight line when $U_{v}$ was plotted against the square root of $T_{v}$, at least up to $\mathrm{U}_{\mathrm{v}}=60 \%$, and that at $\mathrm{U}_{\mathrm{v}}=90 \%$ the theoretical curve occurred at 1.15 times the extrapolated straight line portion. The experimental curve consists of three parts (Fig.2.10b) :
(a)Initial compression : indicated by a short curved line. It results from bedding of the porous stones, compression of air or gas bubbles that may be present or slight particle reorientation; it is assumed that air, and not water is expelled during this stage.

Fig.2.9 One dimensional consolidation isochrones.
(b)Primary compression : commences as soon as water is squeezed out of the soil and is represented by the portion of the curve starting from zero percent consolidation to hundred percent consolidation.
(c)Secondary compression : indicated by the final curved portion of the curve, is the compression that takes place after the excess pore water pressure has reached zero and is thought to be caused by delayed reorientation of the particles due to high viscosity of the adsorbed water layers.

In order to apply the consolidation theory to the laboratory test result the 'root-time curve fitting method' is used as follows (Fig.2.10c) :

1. On the dial gauge reading versus square root of time plot, draw a best fit straight line $\mathrm{R}_{0} \mathrm{P}$ through the initial portion and extrapolate back to a corrected origin $\mathrm{R}_{0}$ to eliminate the initial compression.
2. Draw a straight line $R_{0} R$ from $R_{0}$ with a slope of 1.15 times the slope of the straight portion $\mathrm{R}_{0} \mathrm{P}$ of the experimental plot. This can be easily done by locating point R such that $\mathrm{OR}=1.15 \mathrm{X} \mathrm{OQ}$.
3. The point $S$ (i.e. the intersection of $\mathrm{R}_{0} \mathrm{R}$ and the experimental curve) is considered to be the point corresponding to $90 \%$ consolidation. The abscissa of this point give $\sqrt{\left(t_{90}\right)}$ from which $t_{90}$ is calculated.
4. Now $c_{v}$ is obtained as: $c_{v}=\left(T_{v 90} d^{2}\right) / t_{90}$ where $d$ is the average length of the drainage path, for the load increment and $T_{v 90}$ refers to the value of $T_{v}$ for $U_{v}$ $=90 \%$. From theoretical curve $\mathrm{T}_{\mathrm{v} 90}=0.848$.

## Logarithm of time method

This method was proposed by Casagrande and Fedum (1940). They observed that the curve $U_{v}$ vs. $\log \left(T_{v}\right)$ had three parts (Fig.2.11) :

1. An initial portion with a shape very similar to a parabola and comprises the initial compression.
2. A middle straight line portion attributed to primary consolidation.
3. A lower straight line portion representing secondary compression.

Fig.2.10 Square root of time curve fitting method.

Fig.2.11 Log of time curve fitting method

Calculation of $c_{v}$ from dial reading vs $\log ($ time $)$ plot, the steps followed are :

1. On the initial part of the curve two points $A$ and $B$ are marked at values of time t in the ratio $1: 4$. The vertical distance between these points D is marked above point $A$ to give the initial reading $\mathrm{R}_{0}$ for primary consolidation.
2. For soils displaying secondary compression, it is commonly found that compression continue in a straight line on the $\log$ graph. So this line is extrapolated back to meet the extrapolated straight middle portion. Where these lines intersect is the final reading for primary consolidation $\mathrm{R}_{100}$. For soils which display very little secondary compression, such as heavily over consolidated clays, the final part of the experimental curve will be a horizontal line which will then define the end reading for primary consolidation $\mathrm{R}_{100}$.
3. $\mathrm{R}_{50}$ corresponding to $50 \%$ consolidation is then located mid-way between $\mathrm{R}_{0}$ and $\mathrm{R}_{100}$.
4. The value of $t_{50}$ is noted from the plot corresponding to $R_{50}$. Next $c_{v}$ is determined from $\mathrm{c}_{\mathrm{v}}=\mathrm{T}_{\mathrm{v} 50} \mathrm{~d} / \mathrm{t}_{50}$ where $\mathrm{T}_{\mathrm{v} 50}$ refers to the value of $\mathrm{T}_{\mathrm{v}}$ at $\mathrm{U}_{\mathrm{v}}=50 \%$. From theoretical curve $\mathrm{T}_{\mathrm{v} 50}=0.197$.

The root-time method requires readings over a much shorter time period and less judgement is required.

The conventional units of $c_{v}$ are $\mathrm{m}^{2} /$ year. The value of $\mathrm{c}_{\mathrm{v}}$ varies from increment to increment and is different for loading and unloading. It may vary considerably among specimens of same soil. Actual rate of settlement has been observed to be 2 to 4 times faster than the rate predicted on the basis of $c_{v}$ (Singh, 1992). Typical values of $c_{v}$ (in $\mathrm{m}^{2} /$ year) for undisturbed clays (mont-morillonite) varying with plasticity index are as follows (Lambe and Whitman, 1979; Head, 1982) :
(i) $\operatorname{Ip}>25, \mathrm{c}_{\mathrm{v}}=0.1-1$; (ii) $\mathrm{Ip}=25$ to 5 ; $\mathrm{c}_{\mathrm{v}}=1-10$; (iii) $\operatorname{Ip} \Omega 5, \mathrm{c}_{\mathrm{v}}=10-100$

For silts $\mathrm{c}_{\mathrm{v}}>100$. Disturbed values are about $25-0 \%$ of undisturbed values.

### 2.4 Effect of several factors on the e $\sim \sigma^{\prime}$ relationship and deformation $\sim$ time relationship

### 2.4.1 Effect of sample disturbance

Soil samples collected from the field are somewhat disturbed. Specially, disturbance is inevitable for normally consolidated soil. Sampling disturbance alters and partially destroys the stable arrangement of soil particles and the force or bonds acting between them. Sample disturbance may be the result of combination of a number of factors, mentioned below, in varying degrees (Whitlow, 1995).

## Sampler effects :

(a) Stress relief due to removal of overburden stress.
(b) Shear strain in the soil beneath the tube or piston.
(c) Change in moisture content during sampling: decrease due to pressure on driving, increase due to suction on withdrawal.
(d) Internal vertical shear in soil near to inner face of tube.
(e) Smearing along sides of sample.
(f) Changes in density: increase due to driving pressure, decreases due to lateral expansion at clearance diameter.

## Transport and storage effects:

(a) Ineffective sealing producing change in moisture content.
(b) Mechanical, vibratory or shock damage.
(c) Lateral and vertical moisture movement.
(d) Oxidation and ion transfer from steel tubes.
(e) Crystallization of salts or other compounds that exist in ground water tables.

## Sample preparation :

(a) Density and moisture content changes due to extrusion from sample tube.
(b) Smearing or plucking damage to drainage faces affecting boundary flow.
(c) Shrinkage or swelling.

### 2.4.2 Effect of past loading history

## Normally consolidated clay

Fig.2.12 shows $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ curves that a normally consolidated soil would exhibit in the field (i.e. in situ state), at disturbed state and at remoulded state. If the soil skeleton is disturbed, a relatively flat 'void ratio-effective stress' plot is obtained (Barnes, 1995; Das, 1983). In other words, for a given $\sigma^{\prime}$ the recorded value of e is reduced with the increase in sample disturbance. From Fig.2.12 it can be inferred that e vs. $\log \left(\sigma^{\prime}\right)$ relationship for in situ condition, usually termed as 'virgin compression curve', will lie to the right of the curve for laboratory tested least disturbed soil. Schmertmann (1955) found that irrespective of degree of disturbance all curves coincide at a void ratio of about $0.4 \mathrm{e}_{0}$. He proposed the following method to construct the in situ $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ curve from the curve obtained from laboratory test (Fig.2.13).

1. A consolidation test is carried out with pressures applied which reduce the void ratio to $0.4 \mathrm{e}_{0}$ or at least sufficient values to enable extrapolation to $0.4 \mathrm{e}_{0}$.
2. The present void ratio $\mathrm{e}_{0}$ and effective stress $\sigma_{0}^{\prime}$ are determine and this point A is marked on the graph.
3. The point B at $0.4 \mathrm{e}_{0}$ on the virgin compression curve is marked.
4. The in situ curve is then plotted as the line A-B.

## Overconsolidated clay

Fig. 2.14 shows the nature of field consolidation curve of an over-consolidated clay. The in situ reloading curve commences at the point $\mathrm{A}\left(\mathrm{e}_{0}, \sigma^{\prime}\right)$ and it will have a flatter portion up to $\sigma_{c}{ }^{\prime}$ (point $D$ ), followed by a steeper portion when the soil returns to being normally consolidated. After careful testing, Schmertmann (1953) concluded that the field re-compression branch ( AD in Fig.2.14) has approximately the same slope as the laboratory unload/reload branch. To plot the in situ void ratio versus $\log \left(\sigma^{\prime}\right)$ curve, it is necessary to carry out a consolidation test to produce a reloading curve with pressures applied beyond the pre-consolidation pressure $\sigma_{c}^{\prime}$, followed by an unload/reload loop (BC on Fig.2.14). Further pressure is then applied which reduce

Fig.2.12 Effect óf sampling disturbance on normally consolidated clay (After Barnes, 1995)

Fig.2.13 In situ curve -normally consolidated clay.

Fig.2.14 In situ curve - over consolidated clay.
the void ratio to $0.4 \mathrm{e}_{0}$ or at least sufficient values to enable extrapolation to $0.4 \mathrm{e}_{0}$. The in situ curve is then constructed as follows:

1. Point A having coordinate ( $\mathrm{e}_{0}, \sigma_{0}^{\prime}$ ) is located first. From A, a line is drawn parallel to the average unload/reload loop BC up to point $\mathrm{D} . \sigma_{c}^{\prime}$ may be obtained from the Casagrande construction.
2. The point $E$ at $0.4 \mathrm{e}_{0}$ on the normal compression line is marked. Line DE is drawn to complete the two limbs AD and DE of the in situ curve.

Barnes (1995) proposed an alternative method if $\sigma^{\prime}$ c cannot be determined very accurately. A point D is chosen and lines AD and DE are drawn. Then, $\Delta \mathrm{e}$ the difference between the trial line and the laboratory test result is plotted against $\log \left(\sigma^{\prime}\right)$. When $\Delta \mathrm{e}-\log \left(\sigma^{\prime}\right)$ curve is symmetrical it is considered that the point D represent the most likely value of $\sigma_{c}^{\prime}$.

### 2.4.3 Effect of magnitude of load increment

Leonards and Altschaeffl (1964) reported striking changes in the shape of the compression time curves for one-dimensional compression tests if the load increment ratio is reduced to a substantially low value. Fig. 2.15 shows the shape of dial reading vs. time curves for undisturbed Mexico City clay. Curve I is for $\Delta \sigma / \sigma^{\prime}=1$. Curve II and III are for load increment ratios of 0.25 and 0.22 , respectively. The position of the end of primary consolidation - i.e. zero excess pore water pressure in curves II and III is somewhat difficult to resolve.

The load increment ratio is reported to have influence on the consolidation of clay (Das, 1983). Fig. 2.16 shows the nature of the e vs. $\log \left(\sigma^{\prime}\right)$ curve for various values of $\Delta \sigma / \sigma^{\prime}$. If $\Delta \sigma / \sigma^{\prime}$ is small, the ability of individual clay particles to readjust to their positions of equilibrium is small, which results in a smaller compression as compared to that for a large $\Delta \sigma / \sigma^{\prime}$. The $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ relationship become more distinct when smaller load increments are applied, especially for normally consolidated clays. This is very important when pre-consolidation pressure and in situ curve is to be determined for lightly over consolidated clays.

Fig.2.15 Effect of $\Delta \sigma / \sigma^{\prime}$ on consolidation curves for Mexico city clay. (After Leonards and Altschaeffl, 1964).

Fig.2.16 Effect of load increment ratio on void ratio vs. $\log \sigma^{\prime}$ curve (Das, 1983).

### 2.4.4 Effect of sample thickness

Das (1983) pointed out that for similar load increment ratios, the ratio of secondary to primary compression increases with the decrease of sample thickness (Fig.2.17). Also the ratio of secondary to primary compression increases with decrease of $\Delta \sigma / \sigma^{\prime}$.

### 2.4.5 Effect of load duration

In conventional testing, the soil specimen is left under a given load for about a day (24 hour) and then the next load increment is added. In this case certain amount of secondary consolidation takes place before the next load increment is added. If the specimen is left under a given load for more than a day, additional secondary consolidation settlement will occur. This additional amount of secondary consolidation will have an effect on the e $\sim \log \left(\sigma^{\prime}\right)$ curve as shown in Fig.2.18.

## Chapter 3

## EQUIPMENT AND TEST MATERIAL

### 3.1 Introduction

Reconstituted soils are those which are prepared by breaking down natural soils, mixing them as slurry and reconsolidating them. Reconstituted soils are different from both remoulded and resedimented soils. Soils that are mixed as a suspension and allowed to settle from that state are called resedimented soils. Jardine (1985) discussed the difficulties of implementing detailed investigations of general stressstrain and strength properties using intact samples and it was found that the most comprehensive studies invariably employed reconstituted soil. Reconstituted soil enables a general pattern of behavior to be established. Also comparisons with the response of intact samples may be used to identify any special features associated with fabric, stress history or bonding. The major advantages of using data from reconstituted soil are that the ambiguous and substantial effects of sampling of natural soils and inhomogeneity can be eliminated, while the essential history and composition of in-situ soils can be represented. The disadvantages are that the important effect of post-depositional process, such as ageing, heaving, etc. and of variations of composition and fabric are not included.

### 3.2 Test material

## Sample collection and preparation for making slurry

Natural clay deposit was collected from the site of Bangabandhu Sheikh Mujibur Rahman Novotheatre Project at Bijoy Sarani, Dhaka which was under construction at the time of sample collection. A large area was excavated for the construction of the basement of the project and the samples were collected from the foundation level of the north east quadrant of the dome area (which is at a depth of about 30 ft from the nearby road surface). The colour of the clay is grey and in the in situ state it was identified as medium to stiff clay. After bringing in the laboratory, the clay was dried
in the sun. Next it was powdered by using a wooden mallet. The powdered clay was then sieved through a No. 100 sieve and stored for preparation of slurry.

## Physical / Index properties of the clay used for slurry

Grain size distribution : The grain size distribution of the clay used for slurry is shown in Fig.3.1. More than $98 \%$ of the material is finer than No. 200 sieve ( 0.075 mm ). According to MIT soil classification majority of the particles are of silt size.

Atterberg limits : Liquid and Plastic limits of the clay used for slurry were determined. The liquid limit (LL) of the clay was found to be $49.8 \%$. The plastic limit (PL) was found to be $27.2 \%$. The plasticity index (PI) was $22.5 \%$. On the plasticity chart used by Unified Soil Classification (USC) system (originally proposed by Wagner,1957), the value of PI for the soil used plots on the intersection of A line (which is the border line between silt and clay) and $\mathrm{LL}=50$ line. Thus, the soil lies on the borderline of CL, CH, ML and MH (Fig.3.2).

### 3.3 Preparation of soil slurry

Clay slurry with an initial water content well beyond the liquid limit has been commonly used as an initial state for sample preparation (Siddique, 1990; Hopper,1992). Higher initial water content provides higher degree of saturation and higher freedom of particle orientation but require larger initial volume and longer consolidation period. Since it was planned to prepare several consolidation specimens from the same soil cake obtained from consolidation of slurry, it was essential to use such an initial water content so as to be was just sufficient to yield a uniform and homogeneous slurry. It also was required to reduce the consolidation time required for the preparation of the soil cake.

Around 6.5 kg of air-dry clay powder was mixed with 3500 cc of water for preparation of soil cake with 50 kPa and 100 kPa consolidation pressure. The water added is more than the liquid limit of the clay. The soil and water were thoroughly mixed by hand kneading to form a slurry ensuring full saturation. The slurry was then

Fig.3.1 Grain size distribution of soil used.

Fig.3.2 Plasticity chart used by Unified classification system
mixed, by using a rotary laboratory mixer machine, for about 30 minutes. Farooq (1995) has mentioned the process of slurry preparation in detail.

### 3.4 The Rotary Laboratory Mixer

A Hobart mixer machine was used for making soil slurry. The rotary blades of this machine ensured proper mixing of soil particles with water over a short period of time at the required moisture content. The mixer machine used has a dimension of 738 mm x $406 \mathrm{~mm} \times 489 \mathrm{~mm}$ and includes a three speed gear box driven by a fully enclosed and ventilated motor. The shift handle is mechanically interlocked with the switch, giving definite gear location and making it necessary to switch off the motor before changing gear. The beater shaft is carried on ball bearings. The bowl locks at the top and bottom of lift travel, which is controlled by convenient hand lever. The speed used for preparing slurry was 113 revolutions $/ \mathrm{min}$ for attachment and 198 revolution $/ \mathrm{min}$ for beater. The mixing time was approximately 30 minutes. A photograph of the rotary mixer machine is shown in Fig. 3.3 shows photographs of the attachment and bowl of the mixer machine.

### 3.5 Apparatus for consolidation of slurry

The apparatus consists of a $\mathrm{K}_{0}$-consolidation cell with a loading frame arrangement. The consolidation cell was prepared from a segment of a steel pipe. Its intemal diameter is 203 mm ( 8 inch ) and height 305 mm ( 10 inch ). Two different cells were used. For preparation of soil cakes with 50 kPa and 100 kPa a cell of 260 mm internal diameter and 305 mm ( 12 inch) high was used. A metal tray was required on which the $\mathrm{K}_{\mathrm{o}}$-consolidation cell (containing the soil slurry) was placed.

### 3.6 Consolidation of slurry

A geotextile filter and a 6 mm thick perforated steel disc were placed at the bottom of the $\mathrm{K}_{0}-$ consolidation cell. The wall of the cell was coated with a thin layer of silicon

Fig.3.3 The Hobert laboratory mixer machine (a) Complete set up (b) Bowel and attachment
grease to minimize side friction. A geotextile filter was placed over the disc at the bottom of the cell. The slurry was then poured into the $\mathrm{K}_{0}$-consolidation cell. Next the slurry was stirred with a steel rod to remove the entrapped air. After removing air bubbles, the top surface of the soil slurry was leveled properly by light tamping on the side of the consolidation cell using a wooden hammer. At the top of the slurry, one geotextile filter followed by one perforated disc was placed to permit drainage. A clearance of a few millimeters in between the perforated discs and inside edge of the cell was provided to eliminate side friction. Fig. 3.4 shows a schematic diagram of the arrangements for preparation of reconstituted sample in $\mathrm{K}_{0}$-consolidation cell.

The required axial pressure ( 50 kPa or 100 kPa ) was gradually applied to the sample using a loading frame. At first, the sample was subjected to consolidate by the selfweight of the sample and the weight of the top porous disc for about 24 hours. Then a pressure of 14 kPa was applied to the sample for the next 24 hour. The vertical pressure was increased gradually to the ultimate value of 50 kPa and 100 kPa each time nearly doubling the previous pressure. The pressure was maintained until the end of primary consolidation, which was indicated by the constant reading of a compression dial gauge. It took about nine to ten days for the completion of primary consolidation. Rate of compression was very fast at initial stage of consolidation and gradually it decreased with time. After the completion of consolidation, the top and bottom parts of the cell were separated and the soil cake was extruded by using a mechanical extruder. A soil cake of about 140 mm to 165 mm ( 5.5 to 6.5 inch) thickness was obtained by the above mentioned procedure for preconsolidation pressures of 50 kPa and 100 kPa .

### 3.7 Test program

Standard one dimensional consolidation tests were performed on specimens ( 2.5 inch diameter and 1 inch height) cut from the reconstituted soil cakes. Fig. 3.5 shows a photograph of the apparatus used. The bottom porous stone was slightly larger than the outside diameter of the consolidation ring and thus the tests performed can be termed as of fixed ring type. The porous stones were boiled with water and kept under water till setting of the specimen to avoid intrusion of air bubbles. Table 3.1 shows the

Fig.3.4 Schematic diagram of the assembly of $\mathrm{K}_{0}$ consolidation cell and other components.

Fig.3.5 Photograph of the consolidation cell used
initial pressure, pressure increment ratio, final pressure etc. of consolidation tests performed on specimens having different pre-consolidation pressure. The maximum pre-consolidation pressure employed ( 100 kPa ) was restricted by the available static weights and from consideration not to damage the floor of the laboratory.

## Chapter 4

## LABORATORY INVESTIGATION AND TEST RESULT

### 4.1 Introduction

The results of the laboratory tests performed are presented in this chapter. Effect of variation of stress increment ratio on the nature of $e \sim \sigma^{\prime}$ relations, and values of compression index $\mathrm{C}_{\mathrm{c}}$, coefficient of consolidation $\mathrm{c}_{\mathrm{v}}$ are presented. Also the range of variation of pre-consolidation pressure estimated by Casagrande's method shown.

## 4.2 e~ $\sigma^{\prime}$ relations

In Figs. 4.1a through 4.2b, the void ratio $e$ at the end of consolidation for each pressure $\sigma^{\prime}$ in a consolidation test is plotted in various forms (such as arithmetic, semi-log and $\log -\log$ ) to identify any effect of stress increment ratio and to find any trend. As seen from these figures the $e \sim \sigma$ ' relationship varied for different specimens. Although all the specimens (presented in Fig.4.1) were cut from the same soil cake prepared under 100 kPa normal stress, the initial void ratio among specimens varied which was unexpected. Potential sources could be errors in weight measurements, but carefully obtained measurements for the second series of tests on specimens cut from the soil cake prepared under 50 kPa normal stress also showed similar variations (Fig.4.3). There may be another potential cause that all specimens from the same soil cake prepared under 100 kPa (or 50 kPa ) normal stress, were not tested at the same time because of non-availability of consolidation apparatus. The specimens, though kept in dessicator, dried to some extent reducing the initial void ratio. However, all the curves either for specimens with $\sigma_{c}^{\prime}=100 \mathrm{kPa}$ or 50 kPa are nearly parallel indicating vary little or no effect of stress increment ratio on the shape of e $\sim \log \left(\sigma^{\prime}\right)$ or $e \sim \sigma^{\prime}$ curves at least for the range of stress increment ratio employed in this study. In figures $4.1 a$ and $b$, curves for different stress increment ratio are made identical (i.e. light/deep/dotted line) to easily distinguish them.

Normalized plots (normalizing e and $\sigma^{\prime}$ by $\mathrm{e}_{0}$ and $\sigma_{c}^{\prime}$ respectively) of e and $\sigma^{\prime}$ has been presented in Figs.4.3a through 4.4 c which were made as an attempt to offset the effect of difference in initial void ratio.

### 4.3 Compression index, $\mathrm{C}_{\mathrm{c}}$

The compression index, $\mathrm{C}_{\mathrm{c}}$ calculated from the bottom straight line portion of e $\sim \log \left(\sigma^{\prime}\right)$ plots from different tests are presented in Table 4.1. The values of $\mathrm{C}_{\mathrm{c}}$ obtained ranges from 0.293 to 0.368 and may be considered to be within usual scatter of test data. Therefore, pre-consolidation pressure $\sigma_{c}^{\prime}$ (of a soil layer) up to 100 kPa or stress increment ratio $\sigma_{i+1}^{\prime} / \sigma_{i}^{\prime}$ (in a consolidation test) up to 4 appear to have no effect on the value of $\mathrm{C}_{\mathrm{c}}$ for a natural clay deposit.

Table 4.1 : Values of compression index $\mathrm{C}_{\mathrm{c}}$ from the tests performed.

### 4.4 Pre-consolidation pressure, $\sigma^{\prime}{ }_{c}$

Pre-consolidation pressure, $\sigma^{\prime}$ c were determined from the test data by Casagrande method to have an idea about the level of accuracy of this method. The method is somewhat subjective in locating the point of maximum curvature. The values of $\sigma_{c}^{\prime}$ obtained by Casagrande method is compared in Table 4.2. For tests on specimens prepared with $\sigma_{c}^{\prime}=100 \mathrm{kPa}$ the values from Casagrande's method showed widespread
variations ranging from $65 \%$ to actual; all the predicted values being on the lower side. For tests on specimens prepared with $\sigma_{c}^{\prime}=50 \mathrm{kPa}$ the values from Casagrande's method ranged between $80 \%$ to $120 \%$ of actual.

|  |  | 2 |  |  |  |  |  |
| P100T09 | 100 | 2 | 90 | P50T09 | 50 | 4 | 60 |

### 4.5 Coefficient of consolidation, $c_{v}$

It has been observed that for normal stresses below the pre-consolidation pressure the dial reading $\sim \log$ (time) or $\mathrm{e} \sim \log$ (time) curves do not resemble to the theoretical curve of $U \sim \log \left(T_{v}\right)$ ( $U$ is the degree of consolidation and $T_{v}$ is the time factor.). In such cases, determination of void ratio corresponding to $0 \%$ and $100 \%$ consolidation and thus $\mathrm{T}_{50}$ cannot be made in most cases and even when managed to be made may lead to large error. It may me inferred that, log time method of fitting for determination of $\mathrm{c}_{\mathrm{v}}$ is not suitable for stress levels below the pre-consolidation pressure of an overconsolidated soil.

The values of coefficient of consolidation determined from test data are presented in Fig.4.5 (for specimens with $\sigma_{c}=100 \mathrm{kPa}$ ) and Fig.4.6 (For specimens with $\sigma_{c}{ }_{c}=50$ kPa ). Note that the curves for tests with different stress increment ratio are plotted with different colour density (light / deep) for ease of distinguishing. There is not any discernible difference between the $\mathrm{c}_{\mathrm{v}}$ values obtained from tests with stress increment ratios in the range of 2 to 4 .

## Chapter 5

## A MODEL FOR ONE DIMENSIONAL CONSOLIDATION

### 5.1 Introduction

A mathematical model that can simulate the series of deformation $\sim$ time response under different pressure, as observed in a one-dimensional consolidation test, is presented in this chapter. The role or significance of the model parameters in representing a particular $\mathrm{e} \sim \log ($ time $)$ response are explained. $\mathrm{e} \sim \log (\mathrm{t})$ and $\mathrm{e} \sim(\sigma)$ plots obtained from test and those back calculated using the model are compared. Also effect of variation in test conditions on model parameters are presented.

### 5.2 Proposed model for one-dimensional consolidation and its background

Kondner (1963) first showed that nonlinear stress~strain curves of both sand and clay may be approximated by the following hyperbolic equation

$$
\begin{equation*}
\sigma_{1}-\sigma_{3}=\frac{\varepsilon}{a+b \dot{\varepsilon}} \tag{5.1}
\end{equation*}
$$

Where $\sigma_{1}=$ major and minor principal stress, $\sigma_{3}=$ minor principal stress, $\varepsilon=$ the axial strain , $a$ and $b=$ constants whose values may be determined experimentally

The constants a and b have readily visualized physical meaning. As shown in Fig.5.1 and Fig.5.2, $a$ is the reciprocal of the initial tangent modulus $E_{i}$ and $b$ is the reciprocal of the asymptotic value of stress difference which the stress-strain curve approaches at infinite $\operatorname{strain}\left(\sigma_{1}-\sigma_{3}\right)_{\text {ult }}$

Fig.5.1 Hyperbolic stress-strain curve.

Fig.5.2 Transformed hyperbolic stress-strain curve.

Fig. 5.3 Graphical representation of various functions presented in equations 5.2 a through 5.2 d .

When $a=1 / E_{\max }$ and $b=1 / q_{\max }$ are used equation 5.1 can be rewritten by using normalized stress and strain; $y=q / q_{\max }$ and $x=\varepsilon / \varepsilon_{r}$ where $\varepsilon_{\mathrm{r}}=\mathrm{q}_{\max } / \mathrm{E}_{\max }$ as

$$
\begin{align*}
& y=\frac{x}{1+x}=1-\frac{1}{1+x}  \tag{5.2a}\\
& \frac{y}{x}=\frac{E_{\sec }}{E_{\max }}=\frac{1}{1+x}=1-y  \tag{5.2b}\\
& \frac{x}{y}=1+x  \tag{5.2c}\\
& \frac{1}{y}=\frac{1}{x}+1 \tag{5.2d}
\end{align*}
$$

The shapes of the curves represented by the various functional representations of $x$ and y can be seen from Fig. 5.3.

While the method of obtaining the values of $a$ and $b$ from linear regression analysis of measured stress $\sim$ strain data has been widely in use (Duncan \& Chang, 1970), it has been pointed out (Kondner, 1963) that the initial maximum modulus measured at truly very small strains is greater than the fitted value of $1 / \mathrm{a}$. Also the asymptotic value of $\mathrm{q}=\sigma_{1}-\sigma_{3}$ is larger than the measured strength of the soil by a small amount. This would be expected, because the hyperbola remains below the asymptote at all finite values of strain. Thus the hyperbolic equation as stress $\sim$ strain model can be modified by introducing correction factors $c_{1}=1 /\left(a \cdot E_{\max }\right)$ and $c_{2}=1 /\left(b . q_{\text {max }}\right)$ that is
$\mathrm{y}=\frac{\mathrm{x}}{\frac{1}{\mathrm{c}_{1}}+\frac{\mathrm{x}}{\mathrm{c}_{2}}}$
The above equation with constant coefficient of corrections (i.e. $c_{1}$ and $c_{2}$ being same for all values of $x$ ) can not model the stress $\sim$ strain relationship for the entire range of strain upto peak and specially at small strain as has been shown by Tatsuoka and Shibuiya (1991). Tatsuoka and Shibuiya (1991, 1992) proposed a general type of hyperbolic equation, which is able to model a given stress $\sim$ strain relation from very small strains to around peak stress which in a simplified form is
$y=\frac{x}{\frac{1}{c_{1}(x)}+\frac{x}{c_{2}(x)}}$
where $y=$ normalized shear stress $=\tau / \tau_{\text {max }}$,

$$
\begin{aligned}
& \tau=\text { shear stress }=\left(\sigma_{1}-\sigma_{3}\right) / 2 \\
& \tau_{\max }=\text { shear strength } \\
& \mathrm{x}=\text { normalized shear strain }=\gamma / \gamma_{\mathrm{ref}} \\
& \gamma=\text { shear strain }=\varepsilon_{1}-\varepsilon_{3} \\
& \mathrm{G}_{\max }=\text { maximum shear modulus }
\end{aligned}
$$

and $\mathrm{c}_{1}(\mathrm{x})$ and $\mathrm{c}_{2}(\mathrm{x})$ are correction factors which vary with strain level.

The hyperbolic relationships discussed above when plotted as $y / x \sim \log (x)$ shows the shape of a typical $\mathrm{e} \sim \log (\mathrm{t})$ relations from a one dimensional consolidation test. Therefore, it was stipulated that the change in void ratio for any particular stress increment can be modelled using the relationship
$\mathrm{e}-\mathrm{C}_{3}=\frac{1}{\frac{1}{\mathrm{C}_{1}}+\frac{\mathrm{t}}{\mathrm{C}_{2}}}$
However a new constant $\mathrm{C}_{3}$ is needed to be introduced here. The necessity of this parameter is explained in section 5.3.

### 5.3 Interpretation of model parameters

The model has three parameters here designated as $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$. The significance of these parameters can be understood from Fig.5.4 to Fig.5.5.
Equation 5.4 can be rearranged as follows :
$\frac{1}{e-C_{3}}=\frac{1}{C_{1}}+\frac{t}{C_{2}}$
Equation 5.5 represents a straight line in $1 /\left(\mathrm{e}-\mathrm{C}_{3}\right)$ vs t space (Fig.5.4). On such a plot the quantity $1 / C_{1}$ can be readily visualized as the intercept on the $1 /\left(\mathrm{e}-\mathrm{C}_{3}\right)$ axis at $\mathrm{t}=0$. Also, the parameter $\mathrm{C}_{2}$ represents the inverse of the slope of the fitted straight line.

Referring to equation 5.5 as $t$ approaches 0 (zero) $C_{1}$ approaches $e_{0}-C_{3}$. Also, from equation 5.4, as $t$ tends to infinity $e$ approaches $C_{3}$ i.e. $C_{3}$ represent the end void ratio under a particular load increment (See Fig.5.5). Thus for a particular load increment

Fig.5.4 Graphical representation of equation 5.4 as $1 /\left(e-C_{3}\right)=1 / C_{1}+t / C_{2}$ vs. $t$

Fig.5.5 Graphical representation of equation 5.4 as $e-C_{3}=1 /\left(1 / C_{1}+t / C_{2}\right)$ vs. $\log (t)$
$\mathrm{C}_{1}$ represents the decrease in void ratio from $\mathrm{t}=0$ to the time up to which consolidation continued under that load increment. Mathematically $C_{1}$ and $C_{3}$ are related as $C_{1}=e_{0}-$ $C_{3}$. In general the initial and final void ratios are controlled by the parameters $C_{1}$ and $\mathrm{C}_{3}$.

Figures 5.6, 5.7 and 5.8 show the effect of variation of $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ on the quantities $e-C_{3}$ and $e$. The series of curves on these figures have some similarity with the $\mathrm{e} \sim \log (\mathrm{t})$ curves (or dial reading $\sim \log (\mathrm{t})$ curves) for successive load increments in a one-dimensional consolidation test.

If, in a one dimensional consolidation test, magnitudes of successive load increments are kept same, then the net change in void ratio for the same amount of elapsed time is expected to be less than that for the previous load increments. This feature is well represented in Fig.5.6b. Note that in this figure values of $C_{1}$ and $C_{3}$ is gradually decreased and $\mathrm{C}_{2}$ is gradually increased. It is thus expected that with proper values of the model constants the entire series of $\mathrm{e} \sim \log (\mathrm{t})$ curves and thus $\mathrm{e} \sim \mathrm{p}$ relations, $\mathrm{c}_{\mathrm{v}}, \mathrm{C}_{\mathrm{c}}$ etc. can be obtained.

Fig.5.7 and 5.8 are presented to demonstrate the effects of individual parameter on the resulting e-C ${ }_{3}$ vs. $\log (t)$ and e vs. $\log (t)$ curves. In Fig.5.7a and $5.8 \mathrm{a}, \mathrm{C}_{1}$ is varied while $\mathrm{C}_{2}$ and $\mathrm{C}_{3}$ are kept constant. Note that, since $\mathrm{C}_{3}$ is same for successive curves, values of $e-C_{3}$ at the final time for each curve coincided at $e-C_{3}=0.0$ and values of $e$ at the final time for each curve coincided at $\mathrm{e}=0.8$ (which was the value of $\mathrm{C}_{3}$ for each of these curves). Also note that decrease in value of $\mathrm{C}_{1}$ for successive curve caused the starting point of that curve to shift downward.

In Fig.5.7b and Fig.5.8b, for all the curves, $\mathrm{C}_{1}=0.17$ and $\mathrm{C}_{3}=0.8$ is used but $\mathrm{C}_{2}$ is varied from 0.85 to 3.5 . The effect is that the starting and the end points of these curves are same (because values of $\mathrm{C}_{1}$ are same and values of $\mathrm{C}_{3}$ are same). It is clear that the parameter $\mathrm{C}_{2}$ controls the shape of the curve in between the two end points. For any value of $t$, the curve that has higher value of $\mathrm{C}_{2}$ corresponds to a lower value of e (Fig.5.8b).

Fig.5.8 Plots showing the effect of variation of a single parameter on $\mathrm{e} \sim \log (\mathrm{t})$ rel (a) $\mathrm{C}_{2} \& \mathrm{C}_{3}$ constant, $\mathrm{C}_{1}$ varying (b) $\mathrm{C}_{1} \& \mathrm{C}_{3}$ constant, $\mathrm{C}_{2}$ varying varyin (c) $\mathrm{C}_{1} \& \mathrm{C}_{2}$ constant, $\mathrm{C}_{3}$ varying.

In Fig.5.7c and Fig.5.8c curves parameter $\mathrm{C}_{1}=0.17$ and $\mathrm{C}_{2}=2$ for all the curves whereas $C_{3}$ is varied from 0.8 to 1.5 . As can be found from equation 5.4 e- $C_{3}$ $\left(=1 /\left(1 / C_{1}+t / C_{2}\right)\right)$ is same for any $t$ what ever is the value of $C_{3}$. Therefore, the curves $e^{-} C_{3}$ vs $\log (t)$ coincides for different values of $C_{3}$ (Fig.5.7c). The effect on the successive e $\sim \log (t)$ curves is that they are identical in shape and shifted downward in parallel by the amount of $\mathrm{C}_{3}$ (Fig.5.8c).

### 5.4 Determination of the model parameters

The model parameters $C_{1}, C_{2}$ and $C_{3}$ for any load increment may be determined in any of the three ways described below:
(1) First determine $C_{3}$ as the final void ratio at a load increment. Plot $1 /\left(e-C_{3}\right)$ vs. $t$ and draw a best-fit straight line. Find the intercept on the ordinate (say $m_{1}$ ). Now compute $C_{1}=1 / m_{1}$. Determine the slope (say $m_{2}$ ) of the fitted straight line. Now compute $\mathrm{C}_{2}=1 / \mathrm{m}_{2}$.
(2) Determine $C_{3}$ as mentioned in (1). Determine $C_{1}$ and $C_{2}$ by any software with function fitting option (such as in ORIGIN or EXCEL).
(3) From test data plot e- $\mathrm{C}_{3} \sim \log (\mathrm{t})$. Assume certain $\mathrm{C}_{1}$ and $\mathrm{C}_{2}$ and calculate $\mathrm{e}-\mathrm{C}_{3}=1 /\left(1 / \mathrm{C}_{1}+\mathrm{t} / \mathrm{C}_{2}\right)$ and plot it on the same graph. Vary $\mathrm{C}_{1}$ and $\mathrm{C}_{2}$ and compare the two curves until a visual best fit is obtained.

In the present analysis the parameters $C_{1}$ and $C_{2}$ were determined by the $3^{\text {rd }}$ method. The values of the parameters determined for different tests are summarized in Table 5.1 and 5.2 for specimens with 100 kPa and 50 kPa pre-consolidation pressure respectively.

### 5.5 Steps for numerical implementation of the model

The may be two ways for numerical implementation of the model when the parameters are known. These are :
(a) $C_{1}, C_{2}$ and $C_{3}$ known for each load increment. Its implementation is straight forward as individual curves can be obtained by putting the parameters in the desired equation (Eqn.5.4). In this case $e \sim t$ relations for any pressure (for which $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ are known) can be obtained without any need of the relationship for the previous load increments. The problem with this method is that the final void ratio on a e $\sim t$ relation for a particular pressure and the initial void ratio on the $e \sim t$ relation for the next pressure may not be exactly same. However, this method should reproduce a particular $e \sim t$ relation and the end void ratio with a greater accuracy. Comparison of
(b) Initial void ratio $\mathrm{e}_{0}$ known. $\mathrm{C}_{1}$ and $\mathrm{C}_{2}$ known for different pressure or as a function of pressure.
(1) For the first load increment compute $\left(\mathrm{C}_{3}\right)_{\sigma^{\prime} 1}=\mathrm{e}_{0}-\left(\mathrm{C}_{1}\right)_{\sigma^{\prime} 1}$; here $\left(\mathrm{C}_{3}\right)_{\sigma^{\prime} 1}$ and $\left(C_{1}\right)_{\sigma^{\prime} 1}$ refer to the values of $\mathrm{C}_{3}$ and $\mathrm{C}_{1}$ for pressure $\sigma_{1}^{\prime}$.
(2) Obtain $e$ for different values of $t$ and plot $\mathrm{e} \sim \log (\mathrm{t})$ for pressure $\sigma_{1}^{\prime}$
(3) Determine $\left(\mathrm{e}_{\mathrm{f}}\right)_{\sigma^{\prime} 1}=1 /\left[1 /\left(\mathrm{C}_{1}\right)_{\sigma^{\prime} 1}+\mathrm{t}_{f}\left(\mathrm{C}_{1}\right)_{\sigma^{\prime} 1}\right]+\left(\mathrm{C}_{3}\right)_{\sigma^{\prime} 1}$
(4) To obtain the $\mathrm{e} \sim \mathrm{t}$ plots for the next pressure $\sigma_{2}^{\prime}$ take $\left(\mathrm{e}_{0}\right)_{\sigma^{\prime} 2}=\left(\mathrm{e}_{\mathrm{r}}\right)_{\sigma^{\prime} 1}$ and repeat steps (1) to (3).

Ideally the value of $t_{r}$ in step 3 should be infinity. However, for practical purposes a large value may be used. In this approach the problem of method (a) is eliminated and the final void ratio for any pressure is same to the initial void ratio for the next pressure. However, in this approach errors accumulate and the deviations from test data increases for higher pressure level.

### 5.6 Comparison between test data and back calculation using model

## e~log(t) relations

Figs.5.9 is provided to show comparison of e vs. $\log (t)$ relations from test data (test designation P100T06) and that calculated using the model and the parameters mentioned in Tables 5.1 and 5.2. In these figures the approach used for back calculation using the model is the one mentioned in step (a) in article 5.5. Fig.5.10 shows similar comparison using approach (b) stated in article 5.5. Plots for similar
comparisons between test data and back calculated data using model approach (a) and (b) (article 5.5) for all tests are given in Appendix.A.

The e $\sim \log (\mathrm{t})$ curves obtained by approach (a) shows excellent matching with the test data (Figs.5.9). However, for approach (b) the curves from the model underestimate the void ratio at any particular time and this error is cumulative as explained in article 5.5. Therefore, deviations from test data increased for $\mathrm{e} \sim \log (\mathrm{t})$ curves of lower $\sigma^{\prime}$ to higher $\sigma^{\prime}$ for approach (b) (Fig.5.10).

## $\mathbf{e} \sim \log \left(\sigma^{\prime}\right)$ relations

Comparison of $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ relations from test data (test designation P100T02) and those obtained from model is made in Figs.5.11 and 5.12 for model approach (a) and (b) respectively. In these figures also, it is observed that model approach (a) has reproduced the $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ relations with great accuracy (Fig.5.11). The nature of deviation from test data for approach (b) (Fig.5.12) is the same as mentioned for $e \sim \log (t)$ relations above.

### 5.7 Variation of model parameters

Attempt has been made to reveal the trend, if any exists, of variation of the model parameters with pressure level and pressure increment ratio so that the parameters can be expressed as functions of effective pressure $\sigma^{\prime}$ i.e. $\mathrm{C}_{1}=\mathrm{C}_{1} \mathrm{f}\left(\sigma^{\prime}\right), \mathrm{C}_{2}=\mathrm{C}_{2} \mathrm{f}\left(\sigma^{\prime}\right)$ and $C_{3}=C_{3} f\left(\sigma^{\prime}\right)$. Typical variation of parameters $C_{1}, C_{2}$ and $C_{3}$ with $\sigma^{\prime}$ are shown in Fig.5.13a, Fig.5.13b and Fig.5.13c respectively. From Fig.5.13a it is observed that $C_{1}$ increases up to a certain effective pressure, reaches a peak and then decreases. $\mathrm{C}_{2}$ has the same trend (Fig.5.13b) as $C_{1}$. However $C_{3}$ continuously decreases with effective pressure (Fig. 5.13 c ), initially at a faster rate up to the pressure level where $\mathrm{C}_{1}$ and $\mathrm{C}_{2}$ reaches the peak and then also decreases but a slower rate.

Plots of $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ in linear, semi-log and $\log$-log scale for all tests are provided in Appendix.B.

Table 5.1: Values of model parameters $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$ from consolidation tests for specimens with 100 kPa pre-consolidation pressure.

## Chapter 6

## CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE RESEARCH

### 6.1 Conclusions

A model has been proposed that can represent the one-dimensional consolidation characteristics of a clay soil. One-dimensional consolidation tests were performed on reconstituted Dhaka clay to verify the model.

The outcome of the research may be summerised as follows:
(1) The mathematical model proposed is $e=1 /\left(1 / C_{1}+t / C_{2}\right)+C_{3}$, (equation 5.4) which has three parameters $\mathrm{C}_{1}, \mathrm{C}_{2}$ and $\mathrm{C}_{3}$.
(2) The significance and role of the parameters is demonstrated through experimental verification using Dhaka clay.
(3) Dependency of the model parameters on pressure level has been demonstrated.
(4) The effect of stress-increment ratio ( 2 and 4 used in the tests) appeared to have little influence on the model parameters. As such it may be suggested that stress increment ratios of 4 instead of 2 may be used in consolidation tests. However, this requires further investigation with various types of soils.
(5) Two approaches have been described (article 5.5) for the numerical implementation of the model. The effectiveness of these methods in reproducing the $\mathrm{e} \sim$ time and $\mathrm{e} \sim \sigma^{\prime}$ relationships, (and therefore determination of parameters such as $\mathrm{C}_{\mathrm{c}}, \mathrm{c}_{\mathrm{v}}$ ) are demonstrated by comparing plots from test data and that generated using the model.
(6) The stress increment ratios employed in the consolidation tests performed, showed no significant effect of on $\mathrm{e} \sim \log \left(\sigma^{\prime}\right)$ relations. Any such effect, even if exists, appears to be masked by the usual variations (due to sample disturbance, inhomogeneity etc.) in identical tests on specimens even from the same soil cake.
(7) Values of $C_{c}$ and $C_{v}$ are not found to depend on the stress increment ratio employed in the test.
(8) Casagrande's method for prediction of pre-consolidation is verified. Estimated pre-consolidation pressure by Casagrande's method varied from the actual preconsolidation pressure within a range of $80 \%$ to $120 \%$.

### 6.2 Recommendations for future research

This research work aimed to establish a mathematical model to represent the onedimensional consolidation behaviour of clays. Following are the recommendations for future research works.
(1) The magnitude and nature of variation of the model parameters for different natural soils need to be studied.
(2) Ageing may have significant effect on the consolidation characteristics of clay deposits and it may be investigated using reconstituted and natural soil of different ages.
(3) The proposed model may be implemented numerically by finite element method. The results of settlements and rates of settlements may be compared with field observations.
(4) The model did not consider the effect of secondary consolidation. It may be modified to incorporate the effects of secondary consolidation.
